We investigate the effectiveness of a microwave cavity as a mediator of interactions between two resonant exchange (RX) qubits in semiconductor quantum dots (QDs) over long distances, limited only by the extension of the cavity. Our interaction model includes the orthonormalized Wannier orbitals constructed from Fock-Darwin states under the assumption of a harmonic QD confinement potential. We calculate the qubit-cavity coupling strength in a Jaynes-Cummings Hamiltonian and find that dipole transitions between two states with an asymmetric charge configuration constitute the relevant RX qubit-cavity coupling mechanism. The effective coupling between two RX qubits in a shared cavity yields a universal two-qubit iSWAP gate with gate times on the order of nanoseconds over distances on the order of up to a millimeter.

1. INTRODUCTION

Quantum computation with single-electron spins confined in semiconductor quantum dots (QDs) [1] has been investigated within a wide range of implementations yielding long decoherence times on the order of microseconds [2–5]. Gallium arsenide (GaAs) [6,7] and silicon [8] are the most common choices of host materials for the QDs. By comparison, charge qubits decohere much faster (within approximately nanoseconds [9–11]) due to the strong coupling between the charge and the electromagnetic fields in the environment [12]. Therefore, the aim of many implementations is substantial protection against electrical noise to achieve long qubit decoherence times in order to be able to perform as many qubit operations (gates) as possible while the qubit is coherent. Experiments show high-fidelity state manipulation and long coherence times for scalable implementations using single or multiple QDs [13–20]. One promising candidate is the resonant exchange (RX) spin qubit, a modification of the exchange-only qubit [21], which allows for all-electric control of the qubit for the price of a triple quantum dot (TQD) scheme. This implementation possesses a high robustness against electrical noise at the sweet spot [22–24] but is still susceptible to electromagnetic fields at the resonance frequency allowing for additional qubit control through radio-frequency or microwave signals [17,22]. It was shown that two-qubit gates between RX qubits can be implemented with the exchange coupling, using a single exchange pulse [25].

The coherent transport of quantum information, e.g., long distance entanglement [26], combined with state preparation and readout is investigated within a wide range of implementations [27] in quantum optics. Adapting techniques from this field, long distance coupling between two solid-state QD spin qubits can be envisioned, which could complement the existing short-range interactions, such as the exchange coupling between nearby QD spin qubits. In order to achieve long distance coupling between spin qubits, a long-range interaction is needed, e.g., the coupling of the qubits to an electromagnetic field with specific photon modes [28] or by the coupling of the qubit to a ferromagnet [29]. In this paper, we focus on long-distance coupling between RX qubits based on the electromagnetic fields in a microwave cavity (Fig. 1).

Coupling spin qubits via electromagnetic cavities has been proposed for spin qubits in nitrogen-vacancy (NV) centers in diamond. NV centers can be coupled with photons in the optical spectrum [30–32], while QD spin qubits usually react to microwave or radio-frequency signals. Since microwave cavities with a high finesse exist [33], this long-range coupling is feasible between QD spin qubits in solid-state materials, e.g., coupling spin qubits to photons in a cavity via electric dipole or gate potentials [28,34,35]. Experiments have shown evidence of strong coupling between qubits in single or double QDs to a microwave cavity through the charge [36–39] or the spin [40,41]. Here, we present an implementation of such a long distance interaction between two RX qubits enabled in a TQD scheme at time scales on the order of nanoseconds.

This paper is organized as follows. In Sec. II we introduce our model for the long distance interaction. Subsequently, in Sec. III we calculate the associated transition dipole matrix elements used to determine the corresponding qubit-cavity coupling parameter and identify the underlying coupling mechanism. Finally in Sec. IV, we combine these results to present a step-by-step prescription for a universal two-qubit

FIG. 1. (Color online) Schematic illustration of the proposed setup for long distance interaction. The setup consists of two linearly arranged TQDs (RX qubits) inside a superconducting stripline cavity. For an optimal setup the two qubits should be located at the field maxima (antinodes) in order to achieve a strong qubit-cavity coupling. The green environment surrounding the RX qubits illustrates the coupling of the qubit to the electromagnetic field of the cavity (blue). As a result, the RX qubit can be coupled by using photons as mediators. The gray layer illustrates the two-dimensional electron gas (2DEG) in which the quantum dots are embedded.
isWAP gate between two RX qubits in a shared cavity. We conclude in Sec. V with a summary and an outlook.

II. MODEL

We consider two linearly arranged triple QDs (TQDs), where each QD has a single available orbital, occupied by three electrons. Both TQDs are assumed to lie in a superconducting microwave cavity with a single available photon mode (see Fig. 1). We describe this system with the Hamiltonian

\[ H = \sum_{i=1}^{2} (H_i + H_{int,i}) + H_{cav}, \]

where \( H_i \) describes the dynamics of the electrons in the \( i \)th isolated TQD, \( H_{int,i} \) is the interaction between the electrons in the \( i \)th TQD and the photons in the cavity, and \( H_{cav} \) describes the photons in the cavity.

For the qubit we use the RX Hamiltonian \([22,24]\) \( H \) derived from the three-site extended Hubbard Hamiltonian which describes a linearly arranged TQD [see Fig. 2(a)]. We work in the RX regime in which only the charge states \((1,1,1)\), \((2,0,1)\), and \((1,0,2)\) are accessible. The spin qubit lives in the subspace with spin quantum numbers \( S = S_z = \frac{1}{2} \), spanned by the states

\[ |0\rangle = |S\rangle_{13}|\uparrow\rangle_2 = \frac{1}{\sqrt{2}} \left( c_{1\uparrow}^\dagger c_{2\uparrow}^\dagger c_{3\uparrow}^\dagger c_{1\downarrow}^\dagger c_{2\downarrow}^\dagger c_{3\downarrow}^\dagger |\text{vac}\rangle, \right. \]

\[ |1\rangle = \frac{\sqrt{2}}{3} |T_\uparrow\rangle_{13}|\downarrow\rangle_2 - \frac{1}{\sqrt{3}} |T_0\rangle_{13}|\uparrow\rangle, \]

\[ = \frac{1}{\sqrt{6}} \left( 2c_{1\uparrow}^\dagger c_{2\uparrow}^\dagger c_{3\uparrow}^\dagger c_{1\downarrow}^\dagger c_{1\downarrow}^\dagger c_{2\downarrow}^\dagger c_{3\downarrow}^\dagger - c_{1\uparrow}^\dagger c_{1\downarrow}^\dagger c_{2\uparrow}^\dagger c_{2\downarrow}^\dagger c_{3\uparrow}^\dagger c_{3\downarrow}^\dagger |\text{vac}\rangle, \right. \]

\[ |2\rangle = |S_{1,1/2}\rangle = c_{1\uparrow}^\dagger c_{1\downarrow}^\dagger c_{3\uparrow}^\dagger |\text{vac}\rangle, \]

\[ |3\rangle = |S_{3,1/2}\rangle = c_{1\uparrow}^\dagger c_{3\uparrow}^\dagger c_{3\downarrow}^\dagger |\text{vac}\rangle, \]

where \( |\text{vac}\rangle \) denotes the vacuum state and \( c_{i\sigma}^\dagger (c_{i\sigma}) \) creates (annihilates) an electron in QD \( i \) with spin \( \sigma \). We have further used the notations \( |S\rangle = (|\uparrow\downarrow\rangle + |\downarrow\uparrow\rangle)/\sqrt{2} \), \( |T_\uparrow\rangle = |\uparrow\rangle \), and \( |T_0\rangle = (|\uparrow\downarrow\rangle + |\downarrow\uparrow\rangle)/2 \) for the singlet and two of the triplet states of the two electrons. Here, \((m,n,l)\) denote the number of electrons in the first \( n \), second \( m \), and third \( l \) QDs. In this basis, we obtain for the Hubbard Hamiltonian \([22,24]\)

\[ \hat{H} = \begin{pmatrix} 0 & t_{1/2} & t_{1/2} \\ 0 & 0 & \sqrt{3}t_{1/2} - \sqrt{3}t_{1/2} \\ t_{1/2} & \sqrt{3}t_{1/2} & 0 \end{pmatrix} \begin{pmatrix} \hat{n} & \hat{n} & \hat{n} \end{pmatrix}, \]

where \( t_{1/2} \) is the hopping between the left (right) and the center QDs, \( \epsilon \) is the energy difference between the outer QDs, and \( \Delta \) is the effective energy difference between the center QD and the outer QDs in which Coulomb repulsion is included [see Eq. 2(a)]. In the RX regime \( |\epsilon| < |\Delta| \) and \( t_{1/2} \ll |\Delta \pm \epsilon| \) states \( |0\rangle \) and \( |1\rangle \) are nearly eigenstates, while states \( |2\rangle \), with a charge configuration \((2,0,1)\), and \( |3\rangle \), with a charge configuration \((1,0,2)\), are only virtually occupied and can be eliminated via a second-order Schrieffer-Wolff (SW) transformation, yielding a Heisenberg model, \( \hat{H}_{\text{Heis}} = J_1 S_1 \cdot S_2 + J_2 S_2 \cdot S_3 \), with the exchange energies \( J_1 \equiv t_{1/2}^2/(\Delta + \epsilon) \) and \( J_2 \equiv t_{1/2}^2/(\Delta - \epsilon) \). In its eigenbasis which we consider our logical qubit space, the Hamiltonian takes the form

\[ H_{RX} = \frac{1}{2} \omega_{RX} \sigma_z, \]

where \( \omega_{RX} \equiv \sqrt{(J_1 + J_2)^2 + 3(J_1 - J_2)^2}/2 \) is the resonant frequency of the qubit. Periodic driving of the detuning \( \epsilon \) and \( \Delta \) allows Rabi transitions between the two eigenstates that are hence interesting for cavity quantum electrodynamics (cQED).

For the resonator we consider a superconducting stripline cavity whose resonance frequency is in the gigahertz regime and matches the energy splitting of the RX qubit \([17,22,24]\). Since the relevant dynamics of the cavity mostly depends on the dynamic of a single electromagnetic mode near the qubit resonance frequency, the Hamiltonian is that of a single mode \([42]\),

\[ H_{cav} = \hbar \omega_{ph} \left( a^\dagger a + \frac{1}{2} \right), \]

where \( a^\dagger (a) \) is the bosonic creation (annihilation) operator of a photon with frequency \( \omega_{ph} \). The associated eigenenergies are \( \hbar \omega_{cav} = \hbar \omega_{ph} (n_{ph} + 1/2) \), where \( n_{ph} \equiv \langle a^\dagger a \rangle \) counts the number of photons with the cavity frequency \( \omega_{ph} \).
For the qubit-cavity interaction, we consider the minimal Hamiltonian in the dipole approximation near the resonance [42]

$$H_{\text{int}} = -\frac{e}{m_{\text{eff}}} \left( \frac{\hbar}{2\varepsilon_0 V \omega_{ph}} \right)^{1/2} \epsilon_p \cdot p (a + a^\dagger), \quad (6)$$

where $\epsilon (\epsilon_0)$ describes the dielectric constant of the material (vacuum), $V$ is the volume of the cavity, and $\epsilon_p$ is the polarization of the photons. In the logical qubit subspace, the dipole matrix element of interest is

$$g_r = -\frac{e}{2m} \left( \frac{\hbar}{2\varepsilon_0 V \omega_{ph}} \right)^{1/2} \langle 0 | \epsilon_p \cdot p | 1 \rangle, \quad (7)$$

which describes the photon-induced transition between our two qubit states $|0\rangle$ and $|1\rangle$.

### III. QUBIT-CA VITY COUPLING

#### A. Phenomenological approach

To describe the coupling of a qubit to the cavity, we quantize the two detuning parameters $\varepsilon, \Delta$. This yields $\varepsilon \to \varepsilon + \kappa (a + a^\dagger)$ and $\Delta \to \Delta + \kappa' (a + a^\dagger)$, where $\kappa$ and $\kappa'$ are parameters that include both the amplitude seen by the qubit for a given polarization and the vacuum amplitude of the electric field and $a^\dagger (a)$ is again the creation (annihilation) operator of a photon in the cavity with frequency $\omega_{ph}$.

Assuming $\kappa (a + a^\dagger) \ll \varepsilon$ and $\kappa' (a + a^\dagger) \ll \Delta$, we can expand the RX Hamiltonian in terms of $\kappa (a + a^\dagger)$ and $\kappa' (a + a^\dagger)$. As a result, we find [24]

$$H_{\text{RX}} = \frac{1}{2} \{\hbar \omega_{\text{RX}} + \delta \omega_{z} \sigma_z + \delta \omega_{+} \sigma_+, \} \quad (8)$$

represented in the eigenbasis of the unperturbed system $\delta \omega_z = (J \delta J + 3j \delta j) (a + a^\dagger) / \omega_{\text{RX}}$ and the transversal coupling $\delta \omega_+ = (\sqrt{3} (J \delta J - j \delta j) (a + a^\dagger) / \omega_{\text{RX}}$. Here, we used $J = (J_1 + J_2) / 2$, $\delta \omega_{z} = \delta \omega_{+} = \delta \omega_{-}$. $\delta \omega_{z} = j \delta j$ and the derivatives $\delta \omega_{z} = (\varepsilon J - \Delta J) / (\Delta^2 - \varepsilon^2)$, $\delta \omega_{+} = \delta \omega_{-} = (\varepsilon J - \Delta J) / (\Delta^2 - \varepsilon^2)$. Neglecting higher-order terms of the expansion which correspond to two-photon processes and higher, we obtain

$$H_{\text{IC}} = \frac{\hbar \omega_{\text{IC}}}{2} \sigma_z + g_s (a + a^\dagger) + \hbar \omega_{\text{ph}} (a^\dagger a + 1/2), \quad (9)$$

with the coupling parameter

$$g_s = (\sqrt{3} (J \delta j - j \delta j) / \omega_{\text{RX}} \quad (10)$$

and a photon-dependent resonance frequency $\omega_{\text{IC}} = \omega_{\text{RX}} - (J \delta J + 3j \delta j) (a + a^\dagger) / \omega_{\text{RX}}$. For certain alignments of the TQD and the cavity, the coupling parameters can be set; for example, for an alignment as in Fig. 3(a) we expect $\kappa' \approx 0$ due to the long wavelengths of the cavity photons, while for the alignments in Fig. 3(b) the coupling parameter $\kappa$ is negligible. In the case $\kappa' = 0$, we obtain

$$g_s = (\sqrt{3} \kappa' \frac{\Delta}{\omega_{\text{RX}}} \frac{\ell_1^2 \ell_2^2}{\omega_{\text{ph}} R_e (\Delta^2 - \varepsilon^2)^2}, \quad (11)$$

and in the case $\kappa = 0$, we find

$$g_s = (\sqrt{3} \kappa \frac{\varepsilon}{\omega_{\text{RX}}} \frac{\ell_1^2 \ell_2^2}{\omega_{\text{ph}} R_e (\Delta^2 - \varepsilon^2)} \quad (12)$$

#### B. Microscopic theory

Coupling the qubits of the RX qubit in the TQD to the cavity via the emission and absorption of a photon requires a strong electric-dipole transition element $g_r$ between the two qubit states. We consider an alignment of the TQDs as shown in Fig. 3(a) with the electric field in the cavity pointing in the $x$ direction. To find a finite electric-dipole transition in this system, the following conditions have to be fulfilled. First, the TQD has to be coupled by interdot exchange interactions, i.e., hopping between neighboring QDs. If we look at the matrix element is approximately proportional to the energy splitting between the qubit states ($\approx \ell_{1r}$) which matches with past calculations with a double quantum dot (DQD) [28]. However, there are still two independent symmetries which have to be broken for a nonvanishing matrix element.

The first symmetry arises from the spin-conserving nature of the electric-dipole transitions and corresponds to inversion symmetry. To distinguish the product states of three electrons in a linearly arranged TQD we use three quantum numbers [43]. The first two are the total spin $S$ and its $z$ component $S_z$, which are identical for the qubit states, while the third quantum number is the total spin $S_{1q}$ of the two electrons in the outer QDs 1 and 3, which distinguishes them, $S_{1q} |0 \rangle = 0$ and $S_{1q} |1 \rangle = 1$; hence, they cannot be transferred into each.
other by an interaction $O$ with $[Q_2, O] = 0$. The influence of states [2] and [3] with asymmetric charge configuration breaks this symmetry for $J_1 \neq J_2$, e.g., through a gate detuning $\varphi \neq 0$.

The second symmetry that needs to be broken is an orbital symmetry between the electrons in the outer QDs. The orbital wave functions of an electron in QDs 1 and 3 have identical parity under the assumption that all three QDs have the same lowest orbital confinement potential. To overcome this symmetry either the confinement potentials of the two outer QDs need to be different or the interdot distance between the TQDs has to be asymmetric; hence, $a_1 \neq a_3$, where $a_i$ is the interdot distance between QD 1 (QD 3) and the center QD (see Fig. 2(b)).

1. Wave functions

To calculate the transition dipole matrix element $g_r \propto \langle 0 | \epsilon_r | 1 \rangle$ between the qubit states, we need orbital wave functions which are pairwise orthogonal since the isolated orbital wave functions have a finite overlap [see Fig. 2(b)]. For orthogonal states, these finite overlaps $S_{ij} = \langle \phi_i | \phi_j \rangle$, and $S_{13} = \langle \phi_1 | \phi_3 \rangle$ have to be zero, which is not the case here. Therefore, we transform the nonorthogonal basis $\{|\phi_i\rangle, |\phi_j\rangle, |\phi_3\rangle\}$ into an orthonormal basis of the Wannier orbitals $\{|\Phi_1\rangle, |\Phi_2\rangle, |\Phi_3\rangle\}$ which fulfill the orthonormality condition $\langle \Phi_i | \Phi_j \rangle = \delta_{ij}$, with $i,j \in \{1,2,3\}$. Here, these states are chosen such that they describe the dynamics in the $i$th QD and converge for long distances to the isolated electron wave functions, $\lim_{a_i,a_r \to \infty} |\Phi_i\rangle = |\phi_i\rangle$. Hence, we obtain in the general case

$$
|\Phi_1\rangle = \frac{1}{N_1} (|\phi_1\rangle + a_1 |\phi_2\rangle + b_1 |\phi_3\rangle),
$$

$$
|\Phi_2\rangle = \frac{1}{N_2} (|\phi_2\rangle + a_2 |\phi_1\rangle + b_2 |\phi_3\rangle),
$$

$$
|\Phi_3\rangle = \frac{1}{N_3} (|\phi_3\rangle + a_3 |\phi_2\rangle + b_3 |\phi_1\rangle),
$$

where $a_i$ and $b_i$ are bounded, real parameters. However, these Wannier states are not uniquely defined since the orthogonality condition yields only a linear equation system with three equations but with nine independent parameters. Three parameters $(N_1, N_2, N_3)$ can be eliminated immediately by the normalization condition,

$$
N_1 = \sqrt{1 + 2a_1 S_1 + 2b_1 S_{13} + 2a_1 b_1 S_r + a_1^2 + b_1^2},
$$

$$
N_2 = \sqrt{1 + 2a_2 S_1 + 2b_2 S_{13} + 2a_2 b_2 S_r + a_2^2 + b_2^2},
$$

$$
N_3 = \sqrt{1 + 2a_3 S_1 + 2b_3 S_{13} + 2a_3 b_3 S_r + a_3^2 + b_3^2}.
$$

In a long distance approximation, we neglect the overlap between QD 1 and QD 3 and set $S_{13} = b_1 = b_3 = 0$. This reduces the number of free parameters by two and yields simpler expressions for the normalization parameter, $N_1 = \sqrt{1 + 2a_1 S_1 + a_1^2}$, $N_3 = \sqrt{1 + 2a_3 S_1 + a_3^2}$, and $N_2 = \sqrt{1 + 2a_2 S_1 + 2b_2 S_{13} + a_2^2 + b_2^2}$. The last parameter we adapt from the condition of maximally localized Wannier orbitals, where we minimize the localization functional [44] $\mathcal{F} = \sum_{i=1}^3 (\langle \Phi_i | \hat{\mathcal{F}} \hat{\mathcal{F}} | \Phi_i \rangle - \langle \Phi_i | \hat{\mathcal{F}} | \Phi_i \rangle^2)$ (see Sec. B 1). We found at lowest order a simple behavior for parameters $a_1$ and $a_3$, in particular, $a_1 = \xi_1 S_r + O(S_1, S_1^2)$ and $a_3 = \xi_3 S_r + O(S_1, S_1^2)$ and $\xi_1 = \xi_3 = \xi_d$, which yields the final condition $a_1/a_3 = S_1/S_r$. As a result, we obtain analytical expressions for the parameters, $a_1 = -2S_1$, $a_2 = S_1/(1 - 2 S_1^2 - 2 S_2^2)$, $b_2 = S_1/(1 - 2 S_1^2 - 2 S_2^2)$, and $a_3 = -2S_1$ within the scope of the approximation. A detailed parameter discussion can be found in Sec. B 2.

2. Transition dipole matrix elements

Having found pairwise orthonormal wave functions in position space we first calculate the matrix elements of the position operator $\hat{x}$ in the one-particle basis which we use to calculate $\langle 0 \mid p_1 \mid 1 \rangle$ and finally $g_r$. Therefore, we express the position operator $\hat{x}$ in the orthonormal basis of the Wannier functions $\{|\Phi_1\rangle, |\Phi_2\rangle, |\Phi_3\rangle\}$, each combined with one of the two spin states $\uparrow, \downarrow$ in order to describe the electron spin dynamics. As a result, we obtain

$$
\hat{x} = \sum_{i,j=1}^3 \sum_{\sigma=\uparrow, \downarrow} x_{ij} c_{i,\sigma}^\dagger c_{j,\sigma}, \quad (15)
$$

where $x_{ij} = \langle \Phi_i | \hat{x} | \Phi_j \rangle$, with $i, j \in \{1,2,3\}$, and the operator $c_{i,\sigma}^\dagger$ ($c_{i,\sigma}$) in Eq. (2) creates (annihilates) an electron in the orthonormalized Wannier orbital with spin $\sigma \in \{\uparrow, \downarrow\}$. In the next step, we construct the qubit states $|0\rangle$, $|1\rangle$ and the asymmetric states $|2\rangle$, $|3\rangle$ in terms of the spin Wannier states $|\Phi_i, \sigma\rangle \equiv |\Phi_i\rangle |\sigma\rangle$. Keeping this in mind, we now express the position operator $\hat{x}$ in the $\{0 \}, \{1 \}, \{2 \}, \{3 \}$ basis as

$$
\hat{x} = \left( \begin{array}{ccc}
\sum_{i=1}^3 x_{ii} & 0 & \frac{1}{\sqrt{2}} x_{12} & \frac{1}{\sqrt{2}} x_{13} \\
0 & \sum_{i=1}^3 x_{ii} & \sqrt{\frac{3}{2}} x_{12} & -\sqrt{\frac{3}{2}} x_{13} \\
\frac{1}{\sqrt{2}} x_{21} & \sqrt{\frac{3}{2}} x_{21} & 2 x_{11} + x_{33} & -x_{31} \\
\frac{1}{\sqrt{2}} x_{23} & -\sqrt{\frac{3}{2}} x_{23} & -x_{13} & x_{11} + 2 x_{33} 
\end{array} \right). \quad (16)
$$

We obtain the elements of the momentum operator in the same basis through the relation $\hat{p} = -i \hbar \{\hat{H}_{\text{full}}, \hat{x}\} [42]$. Here, $\hat{H}_{\text{full}}$ is the full Hamiltonian in this basis given in Eq. (3), and the square brackets denote the commutator. An analytical expression can be obtained and is shown in (D2). The simplified expression in Eq. (D3) can be obtained considering real matrix elements, $x_{ij} = x_{ji}$, with $i, j \in \{1,2,3\}$.

3. Interaction Hamiltonian

We now have almost all the tools for calculating the qubit-cavity coupling $g_r$ in $H_{\text{int}}$. However, due to the Schrieffer-Wolff transformation the qubit states in the expression for the RX Hamiltonian in Eq. (4) are not exactly the states defined in Eq. (2); in particular they have a small contribution from the asymmetric states [2] and [3]. Therefore, we have to shift into the qubit basis by the same transformation and hence compute $\hat{p} = e^S \hat{p} e^{-S} \approx \hat{p} - [\hat{p}, \hat{S}]$, where $\hat{S}$ is the SW transformation matrix [22,24]. Considering only the matrix elements in the logical subspace of the RX qubit $\{0 \}, \{1 \}$ and neglecting all
hopping matrix elements, here denoted as $\tilde{|x_i\rangle}$ the virtually coupled states coupling mechanism. Photons induce dipole transitions between in the top left corner of Eq. (D2), one finds that in the other elements, we obtain as a result (see Appendix D)

\[
\tilde{p}_x = -\frac{\sqrt{3}m}{\hbar} \frac{t_{r}}{\Delta^2 - \epsilon^2} \text{Re}(x_{13})\sigma_y \\
+ \frac{m}{\hbar} \left( \frac{t_{r}}{\Delta^2 - \epsilon^2} \text{Im}(x_{13}) + \sqrt{2}t_r \text{Im}(x_{23}) - \sqrt{2}t_r \text{Im}(x_{12}) \right) \sigma_z \\
- \frac{\sqrt{6m}}{\hbar} t_r \text{Im}(x_{12}) + t_r \text{Im}(x_{23})]\sigma_z, 
\]

where irrelevant terms proportional to the identity operator in the qubit space have been omitted.

Comparing this result for $\tilde{p}_x$ including nonvanishing matrix elements with the one for the bare momentum operator $\tilde{p}_x$ in the top left corner of Eq. (D2), one finds that in the latter, only the imaginary part of the single-electron matrix elements appears, e.g., $\text{Im}(x_{23})$, whereas Eq. (17) also contains the real part of $x_{13}$. Hence, we conclude that the physical mechanism of the coupling between the qubit states of the RX qubit is due to the coupling to the asymmetric states $|2\rangle$ and $|3\rangle$ since in our case $x_{ij} \in \mathbb{R}$, with $i,j \in \{1,2,3\}$ (see Appendix E). In particular, the electromagnetic field of the cavity induces electronic transitions, where one electron from a doubly occupied QD is transferred to the singly occupied cavity induces electronic transitions, where one electron from a doubly occupied QD is transferred to the singly occupied QD and not the empty one, hence between states $|2\rangle$ and $|3\rangle$ (see Fig. 4). In this case, we find

\[
\tilde{p}_x = -\frac{\sqrt{3}m}{\hbar} \frac{t_{r}}{\Delta^2 - \epsilon^2} x_{13}\sigma_y. 
\]

It should be noted at this point that a nonperfect alignment of the TQD or electric field in the $x$ direction, e.g., a tilting angle in the $xy$ plane, gives rise to an imaginary contribution to the dipole transition matrix elements, hence allowing for other electronic transitions [see Eq. (17)]. However, this contribution is small if the projection on the $y$ axis, i.e., the tilt angle, is small.

As a last step, we directly compute the single-particle matrix elements in order to find the qubit-cavity coupling $g_r$. The calculation of the associated matrix element $x_{13}$ with the help of the orthonormalized Wannier functions $|\Phi_i\rangle$ yields

\[
\tilde{p}_x = -\frac{\sqrt{3}m}{\hbar} \frac{t_{r}}{\Delta^2 - \epsilon^2} \tilde{\alpha}_{B}(d_r - a_r)\tilde{S}_x\sigma_y, 
\]

where $\tilde{\alpha}_{B}$ is close to 1. An explicit calculation can be found in Appendix E. Substituting the resulting momentum operator into Eq. (6), we obtain for the interaction Hamiltonian

\[
H_{int} = g_r \sigma_z(a + a^\dagger), 
\]

with the effective coupling strength

\[
g_r = -\frac{\sqrt{3}e E_0}{2\hbar \omega_{ph}} \frac{t_r}{\Delta^2 - \epsilon^2} \tilde{\alpha}_{B}(d_r - a_r)\tilde{S}_r. 
\]

It should be noted at this point that a nonperfect alignment of the TQD or electric field in the $x$ direction, e.g., a tilting angle in the $xy$ plane, gives rise to an imaginary contribution to the dipole transition matrix elements, hence allowing for other electronic transitions [see Eq. (17)].
and the vacuum amplitude of the electromagnetic field in the cavity Eq. 1\equiv(h\omega_{ph}/2e_0V)^{1/2}. Identifying \( g_r = g_s \) from Eq. (11), we find

\[
\kappa = E_0 e^{\frac{a_l - a_r}{2} S_l S_r} \omega_{ph} \varepsilon \Delta^2 - \epsilon^2 \frac{\Delta}{t_{ir}}.
\]  

(22)

On closer examination, the long distance behavior of \( g_r \) is mostly determined by the overlap parameters \( S_{l,r} \propto e^{-a_l^2/\kappa^2} \) from Eq. (A4), while the short distance is mostly determined by the hopping parameters. However, we note that from a realistic point of view the shortest distance in Fig. 5 is given by the size of the QDs, which is far outside the scope of our approximation, \( a_{l,r} \gg 40 \text{ nm} \) for GaAs and \( a_{l,r} > 18 \text{ nm} \) for Si (see Fig. 9 in Sec. B2). Additionally, only \( a_l - a_r \neq 0 \) or \( \varepsilon \neq 0 \) are required to break orbital and spin symmetries, allowing for \( g_r \neq 0 \).

IV. IMPLEMENTATION OF LONG DISTANCE INTERACTION

The coupling of the RX qubit to the electromagnetic field of a surrounding cavity enables the coherent transfer of information between the qubit system and the cavity. Therefore, if two RX qubits are coupled to the same cavity, one can transfer information between them via the electromagnetic field. The distance of this transfer is limited by only the extension of the cavity. Inserting the interaction Hamiltonian (20) into the two-qubit Hamiltonian (1), we obtain

\[
H_{\text{RW}} = \sum_{i=1}^{2} \left[ \frac{\hbar \omega}{2} \sigma_z + i g_i (\sigma_z a - \sigma_z a^\dagger) \right] + \hbar \omega_{ph} a^\dagger a
\]  

(23)

in the rotating-wave approximation, where we neglect the counterrotating terms due to \( g_r \ll \omega_{RX} \approx \omega_{ph} \). Here, \( \sigma_z \equiv (\sigma_+ \pm i \sigma_-)/2 \) are the ladder operators, and \( \omega_i \) are the resonance frequencies of the \( i \)th RX qubit, with \( i \in \{1,2\} \). Hence, we can eliminate the cavity mode by a second-order SW transformation [28,47]. As a result, we obtain

\[
H_{\text{tot}} = H_{1Q} + H_{\text{int}} = \sum_{i=1}^{2} \epsilon_{\text{eff}} \sigma_z^i + g_{\text{eff}} (\sigma_z^i \sigma_z^\dagger + \sigma_z^\dagger \sigma_z^i). 
\]  

(24)

with the Stark-shifted energy \( \epsilon_{\text{eff}} = \hbar \omega_i + g_i^2 (a^\dagger a + 1/2)/[\hbar(M - \omega_{ph})] \) and an effective two-qubit coupling parameter \( g_{\text{eff}} = g_i g_2 \left[ 1/\hbar(\omega_i - \omega_{ph}) + 1/\hbar(\omega_2 - \omega_{ph}) \right] \), where \( g_i \) is the coupling strength between the \( i \)th RX qubit and the cavity. A review of the calculation can be found in Appendix F.

The first expression \( H_{1Q} \) in Eq. (24) yields control over rotations around the \( \sigma_z \) axis of the qubits, while the interaction part \( H_{\text{int}} = g_{\text{eff}} (\sigma_z^1 \sigma_z^\dagger + \sigma_z^\dagger \sigma_z^1) \) leads to a universal two-qubit gate. We obtain for the corresponding time evolution

\[
U(t,t_0) = \exp(-iH_{\text{int}}/\hbar)
\]  

\[
= \begin{pmatrix}
1 & 0 & 0 & 0 \\
0 & \cos(g_{\text{eff}} t/\hbar) & i \sin(g_{\text{eff}} t/\hbar) & 0 \\
0 & i \sin(g_{\text{eff}} t/\hbar) & \cos(g_{\text{eff}} t/\hbar) & 0 \\
0 & 0 & 0 & 1
\end{pmatrix},
\]  

(25)

which after the time \( t_\infty = \hbar \pi/(2g_{\text{eff}}) \) yields the universal iswap gate [48]. In summary, we obtain the iswap gate with the following four steps:

1. Prepare both RX qubits to be off resonant from the cavity frequency, \( \omega_i \neq \omega_{ph} \).
2. Detune both RX qubits to be resonant to the cavity frequency, \( \omega_i \approx \omega_{ph} \).
3. Wait for the time \( t_\infty = \hbar \pi/(2g_{\text{eff}}) \).
4. Detune both RX qubits to be off resonant from the cavity frequency, \( \omega_i \neq \omega_{ph} \).

Together with arbitrary single-qubit gates this allows for universal quantum computation over distances on the order of the extension of the cavity. Figure 6 shows the pulsing time \( t_\infty \) as a function of the detuning \( \Omega_i \equiv |\omega_{ph} - \omega_i|/2\pi \), with \( i \in \{1,2\} \), for specific values of the qubit-cavity couplings \( g_i \). To obtain short gating times, we require either a small detuning \( \Omega_{1,2} \) or a strong qubit-cavity coupling \( g_i \). We find gate times \( t_\infty \approx 1 \text{ ns} \) for \( \Omega \approx 10 \text{ kHz} \) and \( g_i = 1 \text{ MHz} \), which allows for up to \( 10^5 \) gate operations if the qubit decoherence time amounts to \( T_\rho \approx 1 \mu \text{s} [17,22,24] \).

V. CONCLUSION AND OUTLOOK

In this paper, we have proposed and analyzed an implementation of a long distance coupling of two RX qubits. We showed that such a coupling can be achieved by placing two RX qubits into a high-finesse cavity (\( Q \) factor exceeds \( 10^5 \)) with the condition that the resonance frequency of the cavity matches the energy separation of the qubit states. By taking into account

![Fig. 6. (Color online) Doubly logarithmic plot of the gate time \( t_\infty \) of the photon-mediated long distance interaction as a function of the detuning \( \Omega = |\omega_{ph} - \omega_i|/2\pi \). The red, blue, and green lines relate to the correspondingly labeled qubit-cavity coupling frequencies \( g_i/(2\pi f_\infty) \) in Fig. 5. For simplicity, we assume that the two coupling frequencies \( f_i \equiv g_{1,2}/(2\pi f_\infty) \) and resonance frequencies \( \omega_{1,2} \) each are identical, which leads to \( t_\infty = \Omega/8f_\infty^2 \).](https://example.com/fig6.png)
the wave functions associated with the RX qubit, we have obtained a realistic description of the qubit-cavity interaction which yields a microscopic mechanism for coupling the qubit to the cavity, namely, by a transition of an electron between the outer QDs. In particular, the cavity causes a transition between states $|2⟩$ and $|3⟩$, which are coupled to the qubit states by electronic hopping elements.

For the description of the wave functions and in order to estimate the dipole transition matrix element between the qubit states we have used the method of orthonormalized Wannier orbitals to construct the electron wave functions by taking only a small, finite overlap between the original electron wave functions into consideration. As a result, we obtain the qubit-cavity coupling strength as a function of the interdot distances. Realistic parameter settings yield values on the order of megahertz depending on the chosen distance. Combining these elements enables coupling between two RX qubits in the same cavity with gate times $t_g$ on the order of nanoseconds depending on the detuning between the resonance frequency between the cavity and the RX qubits and the qubit-cavity couplings. Realistic parameter choices allow $10^3$ operations in the qubit coherence time.

Since the qubit-cavity coupling mechanism is based on the transitions between the asymmetric states $|2⟩$ and $|3⟩$, which are only virtually occupied in the RX regime, the asymmetric resonant exchange (ARX) qubit [24] should have a strong qubit-cavity coupling since in this implementation the asymmetric states are occupied most of the time. However, this consideration requires a much deeper understanding of the associated wave functions. Nevertheless, we encourage the investigation of these aspects in future studies since they may strongly increase the qubit-cavity coupling strength.

This far, we have considered in our analysis only a spin degree of freedom which is appropriate for GaAs. However, silicon has an additional sixfold degeneracy (twofold in typical QDs) of the ground state, the so-called valley degree of freedom, due to local inequivalent minima (maxima) in the conduction (valence) band [8]. This leads to a more complex structure of the single-electron wave functions [49,50]. In this paper, we considered a nondegenerate ground state (strong valley splitting) with the same valley ground state in all QDs. In future studies, the valley degeneracy can be included since this additional degree of freedom could possibly be helpful, e.g., serving as additional qubits [51,52].

In our analysis, we assumed a harmonic confinement potential of the QDs. Small anharmonicities can give rise to a more complex structure of the wave functions than the one considered here. In future studies, these modified wave functions can be included to acquire more accurate predictions which will hopefully encourage future experimental implementations of such a setup for long distance interaction.

**ACKNOWLEDGMENTS**

We thank M. Milivojević for helpful discussions and the supply of numerical values for the tunneling matrix elements. We acknowledge funding from ARO through Grant No. W911NF-15-1-0149.

**APPENDIX A: ELECTRON WAVE FUNCTIONS**

Here, we calculate the single-electron wave functions of an isolated electron in a QD defined in a two-dimensional electron system with a perpendicular external magnetic field $B$ applied. We assume that the potential of the quantum dot is approximately harmonic. Hence, the corresponding wave functions of the ground state are given by the following expression [46]:

$$\varphi(x, y) = \sqrt{\frac{m_{QD}}{\pi \hbar}} e^{-m_{QD}(x^2+y^2)/2\hbar}. \quad (A1)$$

For $B = 0$, $h_{\omega_{QD}} = \hbar \omega_0$ is the harmonic confinement energy of the QD and typically on the order of $3 \text{meV}$ for GaAs, which corresponds with a QD diameter $a_{QD} \approx 20 \text{nm}$, while the higher confinement energy in Si, e.g., $6 \text{meV}$, yields a smaller diameter, $a_{QD} \approx 9 \text{nm}$. Due to the magnetic field, $B \approx 310 \text{mT}$, which is necessary to split off leakage states [22], the wave functions are not properly described by Eq. (A1), and we have to include the influence of the magnetic field. As a result, we obtain the Fock-Darwin states, which are the harmonic states compressed by a factor $b = \sqrt{\omega_{QD}/\omega_0}$, where $h_{\omega_{QD}}$ is the confinement potential of the QD under the influence of the magnetic field $B$ [53]. Here, the modified confinement potential is $\omega_{QD} \equiv \omega_0^2 + \omega_L^2$, with the Lamor frequency $\omega_L \equiv eB/2m$. Hence, fixing the origin of the coordinate system to the center QD, we obtain for the single-electron wave function in the center QD, $\varphi_2(x, y) = \varphi(x, y)$. The wave functions for an electron in the left dot are shifted by $x \rightarrow x + a_l$ and for the right dot by $x \rightarrow x - a_r$, where $a_l (a_r)$ is the distance from the center dot to the left (right) dot. However, due to the gauge transformation of the magnetic field $A = B(\bar{y}, x \mp a_l, r) \rightarrow B(\bar{y}, x)$ they also obtain a phase shift,

$$\varphi_1(x, y) = \sqrt{\frac{m_{QD}}{\pi \hbar}} e^{-i\pi a_l/2\hbar} e^{-m_{QD}(x+a_l)^2+y^2)/2\hbar} \quad \text{and} \quad \varphi_3(x, y) = \sqrt{\frac{m_{QD}}{\pi \hbar}} e^{i\pi a_r/2\hbar} e^{-m_{QD}(x-a_r)^2+y^2)/2\hbar}, \quad (A2)$$

with the magnetic length $l_B = \sqrt{\hbar/eB}$. For the overlaps between the left and center QDs, $S_l \equiv \langle \varphi_1|\varphi_2⟩$, between the right and center QDs, $S_r \equiv \langle \varphi_3|\varphi_2⟩$, and between the left and right QDs, $S_{13} \equiv \langle \varphi_1|\varphi_3⟩$, we obtain

$$S_{l,r} = \exp \left[ -a_l^2 / 4a_r^2 \right], \quad (A3)$$

$$S_{13} = \exp \left[ -(a_l + a_r)^2 / 4a_r^2 \right], \quad (A4)$$

with the magnetic-field-dependent QD Bohr radius of the electron wave functions

$$a_S = \left( \frac{\hbar}{4 \beta l_B m_{QD}} + \frac{m_{QD}}{\hbar} \right)^{-1/2}. \quad (A5)$$

For $B = 0$, we have $a_S = a_0 = \sqrt{\beta / m_{QD}}$. Typical values are $a_S \approx 9.5 \text{nm}$ for GaAs and $a_S \approx 4 \text{nm}$ for Si. Without loss of generality, we find that the overlaps $S_{l,r}$ and $S_{13}$ are always real due to our choice of the wave functions and our assumptions of identical confinement potentials $\omega_{QD}$ in each QD.

Usually, the overlap $S_{13}$ is negligible; for example, for a symmetric setup, $a_l = a_r$, we obtain for the overlaps of the
neighboring QDs $S_l = S_r \equiv S$ with $S \ll 1$ and for the overlap between the left and right QDs $S_{13} = S^4$, and we only have to consider $S_{13}$ for very small distances between the QDs.

**APPENDIX B: ORTHONORMALIZED WANNIER ORBITALS**

1. Minimizing the localization functional

To determine the orthonormalized Wannier orbitals in the long interdot distance approximation we use as an ansatz

\[
|\Phi_1\rangle = \frac{1}{N_1} (|\psi_1\rangle + a_1 |\psi_2\rangle),
\]

\[
|\Phi_2\rangle = \frac{1}{N_2} (|\psi_2\rangle + a_2 |\psi_1\rangle + b_2 |\psi_3\rangle),
\]

\[
|\Phi_3\rangle = \frac{1}{N_3} (|\psi_3\rangle + a_3 |\psi_2\rangle),
\]

with parameters that are determined by the orthonormalization condition $\langle \Phi_i | \Phi_j \rangle = \delta_{ij}$, with $i, j \in \{1, 2, 3\}$, except for one parameter which we define as $k = a_1 S_l / (a_2 S_r)$. In the next step, we calculate the localization functional $\mathcal{F} = \sum_{i=1}^{3} (\langle \Phi_i | \hat{x}^2 | \Phi_i \rangle - \langle \Phi_i | \hat{x} | \Phi_i \rangle^2)$ as a function of $k$, which is straightforward since the Wannier orbitals are superpositions of Gaussian wave functions. The minimizing conditions, $\partial_k \mathcal{F} = 0$, yield two solutions, $k \sim \pm 1$, in the parameter regime investigated here, $a_l = 45$–120 nm (more details are given in Sec. B 2), where we neglect the negative solution since it corresponds to a vanishing overlap between the wave functions. Figure 7 shows the best parameter settings from the minimizing condition from numerical calculations. In Fig. 8, we plot the coefficients of Eq. (B1) as a function of the interdot distance and $k = 1$.

**FIG. 7.** (Color online) Maximally localized parameter settings for $k$ as a function of the interdot distance $a_l$ with different dynamically fixed values for $a_r$. In the symmetric case, $a_r = a_r$, the optimal setting is $k = 1$, while for the asymmetric case, $a_r < a_r$, the optimal setting is $0.3 \leq k \leq 1$ depending on the asymmetry and the interdot distance. Note that for very long interdot distances $k \rightarrow -1$, which corresponds to $|\Phi_i\rangle \rightarrow |\psi_i\rangle$.

**FIG. 8.** (Color online) (a)–(c) Constitution of the orthonormalized Wannier orbitals. The colored lines illustrate the overlaps $\langle \psi_i | \Phi_j \rangle$ with $i, j \in \{1, 2, 3\}$ as a function of $a_l$ with $a_l = 1.1 a_r$ and $E_{QD} = 3.10 \text{ meV in GaAs}$.

2. Limitation of our model

The limitations of the orthonormalized Wannier orbitals are illustrated in Fig. 9 as a function of the interdot distances. The Wannier orbital wave functions $|\Phi_{i, \sigma}\rangle$ describe only the long interdot distance limit. As a condition for the validity of our approach, we use

\[
a_{i, \sigma}^2 \gtrsim -2a_r^2 \log \left( \frac{1}{2} - S_{i, \sigma}^2 \right).
\]

Figure 9 shows the resulting limitations for a magnetic field of $B = 310 \text{ mT}$ for different settings of the confinement energy $E_{QD}$. Considering $\hbar \omega_{QD} = 3.1 \text{ meV}$, we obtain $a_{i, \sigma} > 40 \text{ nm}$ in GaAs and $a_{i, \sigma} > 18 \text{ nm}$ in Si.

**APPENDIX C: MATRIX ELEMENTS OF THE POSITION OPERATOR $\hat{x}$**

For an estimation of the qubit-cavity coupling, the matrix elements of the position operator from Eq. (15) in the $(|0\rangle, |1\rangle, |2\rangle, |3\rangle)$ basis are needed. Therefore, we express all three-electron states in terms of our orthonormalized Wannier functions. In other words, $c_{i, \sigma}^\dagger (c_{i, \sigma})$ creates (annihilates) an electron in the $i$th Wannier orbital with spin $\sigma$. Hence, we have to calculate the following matrix elements, using Eq. (15):

\[
\langle u | \hat{x} | v \rangle = \sum_{i,j=1}^{3} \sum_{\sigma=\uparrow, \downarrow} x_{ij} \langle u | c_{i, \sigma}^\dagger c_{j, \sigma} | v \rangle,
\]

with $u, v \in \{0, 1, 2, 3\}$. For the sake of brevity, we focus here on one of the two relevant cases $u = 2$ and $v = 3$ for the
FIG. 9. (Color online) Limitation of the use of orthonormalized Wannier orbitals in (a) a GaAs TQD and (b) a Si TQD in a magnetic field $B = 310$ mT for different settings of the harmonic potential energies $\omega_{\text{QD}}$. Here, the area in red shows the case in which the overlap between QD 1 and QD 3 cannot be neglected and our approximation breaks down.

qubit-cavity coupling,

$$
\langle 2 | \hat{x} | 3 \rangle = \sum_{i,j=1}^{3} \sum_{\sigma = \uparrow, \downarrow} x_{ij} \langle \text{vac} | c_{3,\sigma} \downarrow^i c_{1,\sigma} \uparrow \rangle,
$$

Inserting $x$ yields only one nonzero term since all others are zero since $\langle \Phi_{i,\sigma} \downarrow | \Phi_{j,\sigma}^\prime \downarrow \rangle = \delta_{ij} \delta_{\sigma \sigma^\prime}$; hence, we obtain

$$
\langle 2 | \hat{x} | 3 \rangle = -x_{13}.
$$

The calculations for the other matrix elements can be done the same way, in particular, $\langle 0 | \hat{x} | 1 \rangle = 0$, since two electrons have to be transferred (or no electrons have to be transferred and a spin has to be flipped). Combining all matrix element, we find the expression in Eq. (16).

APPENDIX D: MATRIX ELEMENTS OF THE MOMENTUM OPERATOR $\hat{p}$

Through the position-momentum relation $\hat{p} = -i\hat{\nabla} \{ H_{\text{lab}}, \hat{x} \}$ we obtain for the momentum operator in the $x$ direction in the $\{|0\rangle, |1\rangle, |2\rangle, |3\rangle\}$ basis

$$
\hat{p} = \begin{pmatrix} A & B \\ B^\dagger & C \end{pmatrix},
$$

with the $2 \times 2$ blocks

$$
A = \begin{pmatrix} \frac{i}{2\sqrt{2}} \left[ m \left( \beta x_{32} - \beta x_{23} + \beta (x_{32} - x_{23}) \right) \right] & \frac{i}{2} \left[ m \left( \gamma x_{32} - \gamma x_{23} + \gamma (x_{32} - x_{23}) \right) \right] \\ \frac{i}{2} \left[ m \left( \gamma x_{32} - \gamma x_{23} + \gamma (x_{32} - x_{23}) \right) \right] & \frac{i}{2\sqrt{2}} \left[ m \left( \alpha x_{32} - \alpha x_{23} + \alpha (x_{32} - x_{23}) \right) \right] \end{pmatrix},
$$

$$
B = \begin{pmatrix} \frac{3}{2} \left[ m \left( \beta x_{32} - \beta x_{23} + \beta (x_{32} - x_{23}) \right) \right] & \frac{3}{2} \left[ m \left( \gamma x_{32} - \gamma x_{23} + \gamma (x_{32} - x_{23}) \right) \right] \\ \frac{3}{2} \left[ m \left( \gamma x_{32} - \gamma x_{23} + \gamma (x_{32} - x_{23}) \right) \right] & \frac{3}{2} \left[ m \left( \alpha x_{32} - \alpha x_{23} + \alpha (x_{32} - x_{23}) \right) \right] \end{pmatrix},
$$

$$
C = \begin{pmatrix} \frac{3}{2} \left[ m \left( \beta x_{32} - \beta x_{23} + \beta (x_{32} - x_{23}) \right) \right] & \frac{3}{2} \left[ m \left( \gamma x_{32} - \gamma x_{23} + \gamma (x_{32} - x_{23}) \right) \right] \\ \frac{3}{2} \left[ m \left( \gamma x_{32} - \gamma x_{23} + \gamma (x_{32} - x_{23}) \right) \right] & \frac{3}{2} \left[ m \left( \alpha x_{32} - \alpha x_{23} + \alpha (x_{32} - x_{23}) \right) \right] \end{pmatrix}.
$$
In the case of real-valued matrix elements $x_{ij} = x_{ji} \in \mathbb{R}$, with $i, j \in \{1,2,3\}$, in Eq. (D2) we obtain a simpler expression for the parameters in Eq. (D1),

$$A_R = \begin{pmatrix} 0 & 0 \\ 0 & 0 \end{pmatrix},$$

$$B_R = -\frac{i m(l_{x11} - \sqrt{2} l_{x12} - l_{12} - l_{13})}{2 \hbar},$$

$$C_R = \begin{pmatrix} 0 & -i m(l_{x31} + l_{13}) \\ -i m(l_{x32} + l_{23}) & 0 \end{pmatrix}. \tag{D3}$$

Shifting the momentum operator into the qubit basis of the RX regime acquired through a second-order Schrieffer-Wolff transformation \[22\], $\tilde{p} = e^S p e^{-S} \approx p - [p, S]$ with the anti-Hermitian matrix $S$. We obtain

$$\tilde{p} \approx p - [p, S] = \begin{pmatrix} A + s B^\dagger & B C^\dagger \\ B^\dagger - s A & C S - s B - B^\dagger S \end{pmatrix}, \tag{D4}$$

where $s$ is the $2 \times 2$ block in the top right corner of matrix $S$. Inserting the expressions for $A, B, C$, and $s$ we obtain the expression $\tilde{p}_{|0,1|} \approx A + s B^\dagger + B^\dagger C$ given in Eq. (17).

APPENDIX E: CALCULATION OF THE COUPLING STRENGTH $g_r$

In order to obtain the qubit-cavity coupling $g_r$, we have to calculate the matrix elements $x_{ij}$ in Eq. (17), with $i, j \in \{1,2,3\}$, which we can rewrite due to a transformation back into the nonorthogonal basis of $\{|\psi_1\rangle, |\psi_2\rangle, |\psi_3\rangle\}$ as $x_{ij} = \sum_{k,l} q_{kl} |\psi_k\rangle |\psi_l\rangle \langle x | |\psi_k\rangle |\psi_l\rangle$, with $k, l \in \{1,2,3\}$ and $q_{kl} \in \mathbb{R}$. Due to the separability of the Fock-Darwin wave functions in position space, $q_k(x,y) = q_k(x)q_k(y)$, where $q_k(x) \in \mathbb{R}$, the integrations over both space dimensions are independent,

$$\langle \psi_k | \hat{x} | \psi_l \rangle = \int_{-\infty}^{\infty} dx \int_{-\infty}^{\infty} dy \phi_k^*(x, y) x \phi_l(x, y) = \left(\int_{-\infty}^{\infty} dx \phi_k(x) x \phi_l(x)\right) \left(\int_{-\infty}^{\infty} dy \phi_k^*(y) \phi_l(y)\right). \tag{E1}$$

In the next step we prove that this integral is always real under the assumption that the confinement energy $\omega_{QD}$ is identical in each QD, even for a finite homogenous magnetic field. For the integration over $x$, this is true since the wave functions do not acquire a phase in the $x$ direction; hence, it has no imaginary contribution. Proving this statement for the second term, which is just the overlap in the $y$ direction, is more complicated due to the additional phase acquired by the magnetic field. We obtain, e.g., for $k = 1$ and $l = 2$ for the second term,

$$\int_{-\infty}^{\infty} dy \phi_{k,2}^*(y) \phi_{l,2}(y) = \int_{-\infty}^{\infty} dy e^{ia_y y / \hbar} e^{-\hbar y / \hbar} = \int_{-\infty}^{\infty} d\bar{y} e^{-\bar{y}^2 / \hbar} e^{-ia_y \bar{y} / \hbar}, \tag{E2}$$

with $\bar{y} = y - 2 i a_y a_0^2 / \hbar^2$, which is a Gaussian integral shifted along the imaginary axis. Since this integral is real, $x_{ij}$ is also real, and the only relevant matrix element according to Eq. (17) is

$$x_{13} = \frac{1}{N_1 N_3} \left(\langle \psi_1 | + a_1 \langle \psi_2 | + b_1 \langle \psi_3 | \hat{x} (\langle \psi_3 | + a_3 \langle \psi_2 | + b_3 \langle \psi_1 |)\right) \tag{E3}. $$

To calculate $x_{13}$, we first consider the more general case of nonvanishing overlap $S_{13}$ for our calculation and neglect $S_{13}$ later. Inserting the Fock-Darwin functions from Eq. (A2), we find

$$x_{13} = \frac{m \omega_{QD}}{\pi \hbar N_1 N_3} \int_{-\infty}^{\infty} dx \int_{-\infty}^{\infty} dy \left( a_1 \exp \left[-\frac{m \omega_{QD} (x^2 + y^2)}{2 \hbar}\right] + \exp \left[-\frac{m \omega_{QD} (a_1 + x)^2 + y^2}{2 \hbar} + \frac{ia_1 y}{2 \hbar B}\right] \right)$$

$$+ b_1 \exp \left[-\frac{m \omega_{QD} (a_2 - x)^2 + y^2}{2 \hbar} - \frac{ia_2 y}{2 \hbar B}\right] x$$

$$\times \left(a_3 \exp \left[-\frac{m \omega_{QD} (a_3 + x)^2 + y^2}{2 \hbar}\right] + b_3 \exp \left[-\frac{m \omega_{QD} (a_3 + x) + y^2}{2 \hbar} - \frac{ia_3 y}{2 \hbar B}\right] + \exp \left[-\frac{m \omega_{QD} (a_3 - x)^2 + y^2}{2 \hbar} + \frac{ia_3 y}{2 \hbar B}\right]\right). \tag{E4}$$

This integral can be solved straightforwardly since all integrands are Gaussian. As a result, we obtain

$$x_{13} = [-a_1 (a_1 b_3 S_t + a_3 S_t + 2 b_3 + S_{13}) + a_2 (a_1 S_r + S_{13}) + b_1 a_r (a_3 S_r + 2 b_3 + 2)] / 2 N_1 N_3. \tag{E5}$$
Setting $S_{13} = b_1 = b_3 = 0$ and inserting $a_1, a_2, b_2,$ and $a_3$ from Sec. III B 1 for the second step, we obtain

$$x_{13} = \frac{a_1 a_3 S_r - a_3 a_1 S_l}{2 \sqrt{a_1^2 + 2 a_1 S_l + 1} \sqrt{a_3^2 + 2 a_3 S_r + 1}} + \tilde{a}_{rel}(a_1 - a_3) S_r S_l,$$

where $\tilde{a}_{rel}$ can be expanded for $k = a_1 S_r / a_3 S_l \approx 1$ (defined and discussed in Sec B 1),

$$\tilde{a}_{rel} \approx 1 + \left( \frac{a_1}{a_3 - a_1} - S_l^2 + S_r^2 + 1 \over 2 \right)(k - 1),$$

which yields the expression in Eq. (19) after inserting into Eq. (17).

**APPENDIX F: SECOND SW TRANSFORMATION TO ELIMINATE THE CAVITY MODE**

In this Appendix, we present an effective Hamiltonian in which the cavity mode is split off by a second SW transformation in order to express the cavity-mediated coupling between two RX qubits [28]. We start with the universal Hamiltonian in the rotating frame from Eq. (23) and introduce a second-order SW transformation,

$$H_{tot} \equiv e^{S_l H_{GW} E^{-S_l}} \simeq H_0 + [H_{int}, S_2]/2,$$

where $H_0 \equiv \sum_i \hbar \omega_i / 2 \sigma_i + \hbar \omega_{ph} a_i^\dagger a_i$ and $H_{int} = \sum_i g_i \sigma_i a_i^\dagger a_i$ (and the anti-Hermitian operator $S_2$ is determined by the SW condition $[H_0, S_2] = -H_{int}$). Hence, we express $S_2$ in terms of operators,

$$S_2 = \sum_{i=1}^{2} \frac{g_i}{\hbar \omega_{ph} - \hbar \omega_i} (\sigma_i a_i - a_i^\dagger),$$

with the previously introduced ladder operators $\sigma_i \pm$.
